Abstract

This paper surveys portfolio construction methods that extend the traditional approach. An important feature of the traditional approach is that investor's preferences are defined on the mean and variance of random outcomes. However, there are other important features that are not always made explicit regarding investor's wealth, information, and horizon: The investor makes a single portfolio choice based on the mean and variance of her final financial wealth and she knows the relevant parameters in that computation. First, the paper describes the traditional portfolio choice based on the previous four assumptions, while the rest of sections extend those assumptions. Each section describes the corresponding equilibrium implications regarding portfolio advice and asset pricing.

Keywords: Mean-Variance Analysis, Background Risks, Estimation Error, Expected Utility, Multi-Period Portfolio Choice.

JEL: D81, G11, G12

*Part of this survey is based on material of portfolio management courses at BBVA, CEMFI, and University of Alicante. The author thanks Álvaro Elices, Jón Danielsson, Lorenzo de Cristóbal, and Ángel León. The author especially thanks Gonzalo Rubio and Enrique Sentana for detailed comments. Financial support from the MEC ref. SEJ2005-02829/ECON is acknowledged.

1 Introduction

This paper is a survey on portfolio construction methods that extend the traditional approach. An important feature of the traditional approach is that measures the risk and return trade-off in terms of the mean and variance of final wealth, i.e. it takes a particular stand on investor's preferences. Mean-variance theory has been widely used both inside and outside financial economics. Finance applications include topics such as portfolio analysis, asset pricing, and performance measurement.

However, there are other important features of the traditional portfolio choice that are not always made explicit in terms of investor's wealth, information, and horizon: The investor makes a single portfolio choice based on the mean and variance of her final financial wealth and she knows the relevant parameters in that computation. Therefore, we define traditional portfolio choice as based on four assumptions on the investor:

1. Wealth: There are not background risks and all financial assets are tradable (perfectly liquid). Inflation, human capital, liabilities, etc. are not taken into account.
2. Information: Her information set includes all the relevant parameters in the portfolio choice problem. Specifically, she knows the relevant parameters of the joint distribution of asset returns.
3. Preferences: Under the expected utility paradigm, she is only concerned about the mean and variance of random outcomes, i.e. her preferences are mean-variance. The relevant measure of risk is variance.
4. Horizon: Her investment horizon is one period in the sense that she only trades at the beginning of that period and cares about utility from final wealth. The investor does not take into account investment opportunities in future periods.

This ordering of assumptions represents an increasing complexity in the required extensions once that particular assumption is dropped and hence will be the guideline of this survey. Scherer (2004) is a good reference for many of the topics we will cover and Brandt (2005) is another good reference, with a focus on econometric issues related to portfolio choice.

Section 2 describes the traditional portfolio choice and the rest of sections extend one of those assumptions while keeping the rest as given. References that extend several assumptions at the

same time are also provided. Each section describes the corresponding equilibrium implications in terms of portfolio advice (e.g. holding or not the market portfolio) and asset pricing. Even though a survey on portfolio choice could naturally skip asset pricing issues, we consider the feed-back between portfolio choice and asset pricing models as very relevant.

Section 3 extends the first assumption on investor's wealth, while Section 4 extends the second assumption on investor's knowledge of parameters. These two sections still rely on mean-variance preferences, but the next two represent a significant departure. Section 5 extends the third assumption on investor's preferences and Section 6 extends the fourth assumption on investor's horizon.

Obviously, the previous assumptions are not the only ones that are made. First, portfolio choice based on maximizing expected utility is a maintained hypothesis in this paper. The expected utility paradigm is the canonical model of preferences under uncertainty and plays a central role in portfolio choice theory. The reader can find references outside this paradigm in Section 2.4.1 of Brandt (2005).

We also assume perfect markets in the sense of price-taking behaviour and lack of market frictions such as transaction costs, trading constraints, taxes, etc. Some market frictions can be easily included in the analysis as problem constraints, but this survey is not focused on portfolio choice under different types of constraints for a given (mean-variance) criterion. For instance, we will not add value at risk or probability of shortfall constraints. Nevertheless, we dedicate Section 5 to preferences that are not mean-variance, where we can introduce those constraints as the portfolio choice criterion itself. In addition, Section 4 comments briefly the introduction of constraints to alleviate the effects of estimation error.

2 Traditional Portfolio Choice

2.1 Investment Set-Up

Let us first describe the investment opportunities and the required notation. The gross return of a particular asset (payoff divided by price) is denoted by R and the corresponding rate of return by $r = R - 1$. We assume the investor has access to $1 \leq N < \infty$ risky assets, which can be interpreted as asset classes, e.g. stocks and bonds.¹ To simplify the exposition, we assume

¹In a global asset allocation set-up, we would include currencies, stocks and bonds from different countries or regions.

cash (short-term money-market instruments) is also available and plays the role of a safe asset. The risk-free rate of return is denoted by r_0 and an excess return by $e = r - r_0$.

The corresponding vectors of rates of returns and excess returns of risky assets are denoted by \mathbf{r} and \mathbf{e} . The corresponding $N \times 1$ mean vectors and $N \times N$ variance-covariance matrix, which we assume well-defined, are

$$\boldsymbol{\nu} = E(\mathbf{r}), \quad \boldsymbol{\mu} = E(\mathbf{e}), \quad \boldsymbol{\Sigma} = Var(\mathbf{r}) = Var(\mathbf{e}),$$

where $\boldsymbol{\mu}$ is known as the vector of risk premia. We make two simplifying assumptions on those objects, not all expected returns are equal to the riskless return ($\boldsymbol{\mu} \neq \mathbf{0}$), and $\boldsymbol{\Sigma}$ is nonsingular ($|\boldsymbol{\Sigma}| > 0$). The former assumption is required to define a proper risk-return trade-off and the latter one is required to avoid a "hidden" safe asset, i.e. a non-trivial portfolio with zero variance. We also define $H = \boldsymbol{\mu}'\boldsymbol{\Sigma}^{-1}\boldsymbol{\mu}$.

The payoffs that an investor can get are given by portfolios of those assets and financial investment is modelled as a technology with constant returns to scale. Let us define $\mathbf{1}$ as an $N \times 1$ vector of ones and denote the amount of wealth invested in each risky asset by an $N \times 1$ vector \mathbf{w} . Hence $\mathbf{w}'\mathbf{1}$ represents the wealth invested in risky assets and the rest of wealth is invested in the safe asset. If we normalize initial wealth to 1 then $1 - \mathbf{w}'\mathbf{1}$ is the wealth invested in the safe asset, and we can interpret \mathbf{w} as the proportions of wealth invested in risky asset classes.

We can express the rate of return of a unit-cost portfolio as

$$r = \mathbf{w}'\mathbf{r} + (1 - \mathbf{w}'\mathbf{1})r_0 = r_0 + \mathbf{w}'\mathbf{e}, \quad (1)$$

and the corresponding notation for its moments is

$$\begin{aligned} E(r) &= r_0 + \mathbf{w}'\boldsymbol{\mu} = \nu, & E(e) &= \mathbf{w}'\boldsymbol{\mu} = \mu, \\ Var(r) &= Var(e) = \mathbf{w}'\boldsymbol{\Sigma}\mathbf{w} = \sigma^2. \end{aligned} \quad (2)$$

An investor's portfolio choice maximizes expected utility. Here we impose assumptions 1 and 4. The latter assumption defines final period wealth as the object of interest for the investor and the former one allows the focus on financial wealth, i.e. the payoff of the chosen portfolio. Since we normalize initial wealth to 1, her final wealth is equal to her portfolio's gross return R . The portfolio choice problem is simply

$$\max_{\mathbf{w}} E[u(R)] \quad (3)$$

for some von Neumann-Morgenstern (vN-M) utility function² $u(\cdot)$, which is usually strictly increasing and concave to reflect an agent that prefers more to less and shows risk aversion.

2.2 Mean-Variance Portfolio Choice

Now we impose assumption 3, which means that we can represent investor's expected utility as a function of her return's mean and variance $E[u(R)] = U(\nu, \sigma^2)$, where (ν, σ^2) are given in (2) and the function $U(\cdot)$ is such that $\partial U/\partial \nu > 0$, $\partial U/\partial \sigma < 0$, and $U(\nu, \sigma^2)$ is (strictly) concave. This set-up implies that the variance is an accurate measure of risk, which is not true in general. Portfolio choice under mean-variance preferences was developed in Markowitz (1952, 1959) and Tobin (1958) and has been widely used in finance because it delivers simple expressions and rich empirical implications.

A mean-variance investor solves a special version of the problem (3)

$$\max_{\mathbf{w}} U(\nu, \sigma^2)$$

and we can study her indifference curves on (ν, σ^2) or (ν, σ) spaces, where ν is usually drawn on the y-axis.³ We will focus on the space (μ, σ) from now on, which simply changes the origin on the y-axis. She will choose the tangency between her indifference curves and the mean-variance frontier $\sigma^2(\mu)$, which represents the best mean-variance trade-off that investors can get from available assets. See Figure 1, where the dotted curves are indifference curves, the arrow shows the direction of higher expected utility, and the mean-variance frontier is the solid line.

Therefore, we turn to study $\sigma^2(\mu)$. The mean-variance frontier can be represented in three equivalent ways: Minimizing variance for each target risk premia μ to emphasize portfolio diversification

$$\min_{\mathbf{w}} \text{Var}(e) \quad s.t. \quad E(e) = \mu, \quad (4)$$

where the dependence of $\text{Var}(e)$ and $E(e)$ on \mathbf{w} is given by (2), maximizing risk premium for each target variance σ^2 in the spirit of risk budgeting

$$\max_{\mathbf{w}} E(e) \quad s.t. \quad \text{Var}(e) = \sigma^2,$$

²We follow the usual convention in finance references. Other references might use the concept of vN-M utility for $E[u(R)]$ instead.

³We can be more precise with a classical example: vN-M exponential (or CARA) utility $u(R) = -\exp(-\theta R)$, where $\theta > 0$ is the coefficient of absolute risk aversion, plus normally distributed $R \sim N(1 + v, \sigma^2)$. In that context,

$$E[-\exp(-\theta R)] = -\exp\left[-\theta(1 + v) + \frac{1}{2}\theta^2\sigma^2\right],$$

which is an ordinal utility function of (v, σ^2) and can also be represented by $v - 0.5\theta\sigma^2$.

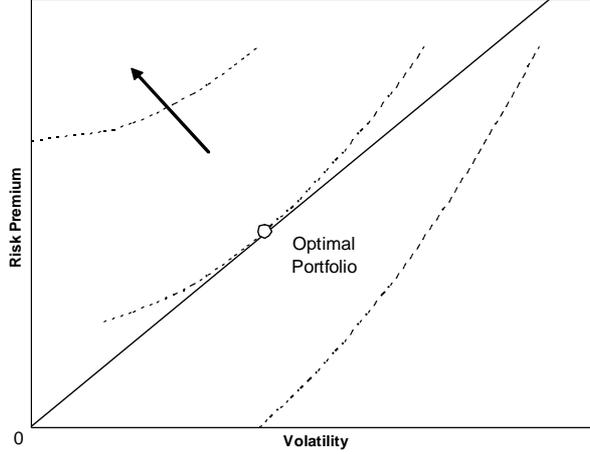

Figure 1: Mean-variance preferences and frontier. The arrow shows the direction of higher expected utility

or maximizing a trade-off between risk and return given by each risk tolerance λ

$$\max_{\mathbf{w}} E(e) - \frac{1}{2\lambda} Var(e).$$

By choosing the corresponding μ , σ^2 and λ , we can make the three solutions equal. The corresponding algebra for a general N was developed explicitly by Merton (1972). A textbook treatment can be found in Chapter 3 of Huang and Litzenberger (1988) and Chapter 4 of Ingersoll (1987). The case of an unbounded N was studied by Chamberlain and Rothschild (1983) by means of Hilbert space theory.

The risky component of the optimal portfolio is

$$\mathbf{w}(\mu) = \left(\frac{\mu}{H}\right) \Sigma^{-1} \boldsymbol{\mu}, \quad (5)$$

in the first representation, while it is $\mathbf{w}(\lambda) = \lambda \Sigma^{-1} \boldsymbol{\mu}$ in the last representation. Stevens (1998) gives an insightful representation of the matrix Σ^{-1} , and hence the vector $\Sigma^{-1} \boldsymbol{\mu}$, in terms of regression hedges. Think of a least squares regression of a particular excess return on a constant and the rest of excess returns. That excess return's entry in $\Sigma^{-1} \boldsymbol{\mu}$ is equal to the ratio of the constant over the residual variance of that regression.

Let us focus on the solution of the first representation. The main property of $\mathbf{w}(\mu)$ is its proportionality to $\Sigma^{-1} \boldsymbol{\mu}$, i.e. the target μ only rescales the previous vector and relative weights in the optimal risky position are constant across the frontier. In fact, we can compute any optimal portfolio from any pair of optimal portfolios, which is known as two-fund spanning.

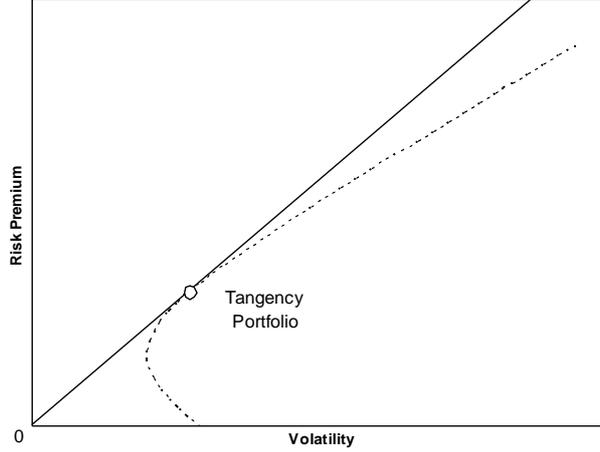

Figure 2: Mean-variance frontiers with and without a safe asset.

However, the natural choice is the safe asset and the tangency portfolio, a portfolio of risky assets that the mean-variance frontiers with and without risky assets share. See Figure 2, where the dotted curve represents the mean-variance frontier without a safe asset. The reader can find the details about that frontier and the characterization of the tangency portfolio in the references.

The mean-variance frontier is the variance corresponding to the optimal portfolio (5) for each target μ

$$\sigma^2(\mu) = \mathbf{w}(\mu)' \boldsymbol{\Sigma} \mathbf{w}(\mu) = \frac{1}{H} \mu^2. \quad (6)$$

The global minimum variance portfolio is simply the safe asset and the frontier is composed by two straight lines on the space (μ, σ) , where it is usually drawn with μ on the y-axis. Of course, we can also draw it on the (μ, σ^2) space, where it becomes a parabola.

Mean-variance efficient portfolios are defined as those portfolios that are not dominated in mean-variance space by any other portfolio. Therefore, (6) shows that the efficient frontier is given by portfolios (5) with $\mu \geq 0$. This part of the frontier is the solid line in Figure 1 and 2. Mean-variance investors' portfolios will be located on the efficient frontier and this (mean-variance) efficient set of portfolios is convex. In addition, we find a trade-off between risk and return on the efficient side of the frontier, i.e. we can only target a higher μ if we are willing to suffer a higher σ^2 .

2.3 Equilibrium Implications

We have not been very explicit about the mean-variance parameters so far. Now we impose assumption 2 and hence all investors use the same mean-variance parameters and they are equal to the true ones. Let us think of a set of investors, each of them with some mean-variance preferences $U(v, \sigma^2)$ and some initial wealth.

In this context, we will study the equilibrium implications of the previous set-up regarding portfolio advice and asset pricing. This theory is called the Capital asset pricing model (CAPM) and was developed by Sharpe (1964), Lintner (1965), and Mossin (1966). More recently, Berk (1997) develops the necessary and sufficient conditions for the CAPM under expected utility. We will focus on the CAPM with a safe asset, the reader can find a CAPM without it in Black (1972). The CAPM provides a precise link of risk and return and hence it is widely applied even though it does not hold empirically as described in Chapter 5 in Campbell et al. (1997) and Chapter 20 in Cochrane (2001).

Let us define the market portfolio as the aggregate supply of risky assets, with weights given by their market capitalization. This concept includes all risky assets in the economy since we assume everything is traded through assumption 1, but the market is understood as listed equities (the stock market) in the usual applications. Under equilibrium, the market portfolio must be equal to the aggregation of agents' demands, which are mean-variance efficient. The convexity of the mean-variance efficient set implies that the market portfolio must be efficient, which is the basic implication of the CAPM. Moreover, if we assume a zero net supply of the riskless asset then the market portfolio is equal to the tangency portfolio. The efficient part of the linear frontier is called the Capital market line (CML).

By two-fund spanning, we can represent every investor's portfolio as a combination of the safe asset and the market portfolio and this type of situation is labelled as two-fund separation. Being more (less) risk averse simply translates into investing less (more) on the market portfolio. Therefore, the portfolio advice of the CAPM is passive investment, i.e. investors should hold the market portfolio. This implication of the CAPM had a big impact in the industry, spurring the use of indexed funds.

In the real world, not every agent invests in the same portfolio of risky assets. Professional advice recommends a higher ratio of stocks with respect to bonds the higher the investor's aggressiveness and investment horizon as Canner et al. (1997) point out. They also stress that

the absence of a riskless asset cannot rationalize this advice because the mix of bonds and stocks would change with risk aversion, but not in the same direction as professional advice. Short-sale constraints on cash positions cannot rationalize the advice either. Moreover, given the historical low Sharpe ratio of bonds compared to stocks, it looks like mean-variance investors should not invest much in bonds. Next sections will show how the theoretical advice gets closer to real world portfolios once we drop some of the traditional four assumptions.

Another big impact of mean-variance analysis in the investment industry has been the development of certain performance measures. One of such measures is the Sharpe ratio (others examples are the Treynor index and the Jensen's alpha), which is defined as a risky portfolio's risk premium per unit of risk

$$SR = \frac{\mu}{\sigma} \quad (7)$$

and was developed in Sharpe (1966) to evaluate mutual funds following the implications of mean-variance analysis. Obviously, we can compare Sharpe ratios of different portfolios without relying on an equilibrium set-up, but this measure is meaningful when we think of the CML. Under mean-variance preferences, there is an optimal benchmark for every agent, the slope of the CML on the (μ, σ) space (\sqrt{H}) . Sharpe (1994) reviewed the literature that this measure generated and clarified its application.

Finally, let us briefly comment the asset pricing implications of the CAPM. In equilibrium, any risky portfolio with excess return e and risk premium μ must satisfy

$$\mu = \beta\mu_M, \quad \beta = \frac{Cov(e, e_M)}{Var(e_M)}, \quad (8)$$

where e_M is the market excess return and μ_M is the market risk premium. Every risk premium is equal to the corresponding beta, the risk measure in the CAPM, times the market risk premium. This linear relationship is called the Security market line (SML).

Unfortunately, the pricing equation (8) is simply a direct implication of the mean-variance frontier algebra, i.e. it is true if we substitute the market portfolio for any frontier portfolio. Moreover, the market portfolio is unobservable and researchers usually work with a stock index as a proxy. Therefore, testing the CAPM is not a straightforward application of (8) as Roll (1977) stressed.

3 Background Risks

3.1 New Framework

Assumption 1 stated that there are not background risks and all financial assets are tradable or perfectly liquid. Obviously, not every risk or asset can be traded and hence a more realistic set-up is a portfolio choice among risky securities (endogenous risks) while facing exogenous and unavoidable background risks.

Let us study a simple way of introducing the latter risks in the portfolio construction. Instead of managing the risk-return trade-off of r , we manage $a = r - b$, where b is the background risk and covers several situations such as:

- Inflation: b is the relevant inflation rate and a the corresponding real return. This case was studied by Friend et al. (1976) and Solnik (1978).
- Human capital: b is minus the return on human capital, which is treated as uninsurable. This case was studied by Mayers (1973) and Brito (1977) as the most important example of a nontradable asset. Friend et al. (1976) also analyze the joint effect of inflation and human capital.
- Liabilities: In the context of asset-liability management (ALM) of a pension fund, Sharpe and Tint (1990) define surplus returns as final surplus $S_1 = A_1 - L_1$ (the difference between assets and liabilities) relative to initial assets A_0 . They can be expressed as $S_1/A_0 = R - (L_0/A_0)(L_1/L_0) = R - b$, where L_1/L_0 is the source of background risk.

Portfolio returns are still given by (1) but the relevant mean and variance are now

$$E(a) = E(r) - E(b) = \delta, \tag{9}$$

$$Var(a) = Var(r) + Var(b) - 2Cov(r, b) = \omega^2.$$

Note that cash is not riskless if our risk measure is ω^2 instead of σ^2 . The new key object is the covariance of risky securities with background risk

$$\gamma = Cov(\mathbf{r}, b)$$

and the notation $F = \gamma' \Sigma^{-1} \mu$ will be used in some expressions.

The previous examples might also require an explicit modelling of long-term or dynamic portfolio choice, i.e. relax assumption 4 at the same time. The corresponding references will be given in Section 6.4.

3.2 Background Risks in a Mean-Variance Framework

This section follows Mayers (1973), Brito (1977), and mainly Solnik (1978). We will focus on the case of a safe asset and the reader can find the case without a safe asset in those references. The optimal portfolio is now given by

$$\min_{\mathbf{w}} \text{Var}(a) \quad s.t. \quad E(a) = \delta,$$

where $\text{Var}(a)$ and $E(a)$ are given by (9), which can be equivalently expressed as

$$\min_{\mathbf{w}} \text{Var}(e) - 2\text{Cov}(e, b) \quad s.t. \quad E(e) = \mu$$

and the only difference with the traditional problem (4) is the component $\text{Cov}(e, b) = \mathbf{w}'\boldsymbol{\gamma}$ in the risk criterion. We skipped the component $\text{Var}(b)$ in $\text{Var}(a)$ and $E(b)$ in $E(a)$ because they are not affected by the portfolio choice. The solution can be represented as

$$\mathbf{w}_b(\mu) = \mathbf{w}(\mu) + \mathbf{w}_h, \tag{10}$$

the traditional optimal portfolio for μ in (5) plus a constant term, a hedging demand due to background risk,

$$\mathbf{w}_h = \boldsymbol{\Sigma}^{-1}\boldsymbol{\gamma} - \left(\frac{F}{H}\right)\boldsymbol{\Sigma}^{-1}\boldsymbol{\mu}.$$

The component $\boldsymbol{\Sigma}^{-1}\boldsymbol{\gamma}$ can be interpreted as the coefficients of \mathbf{r} in the least squares regression of b on a constant and the vector \mathbf{r} . Let us think of a diagonal $\boldsymbol{\Sigma}$ to fix ideas. Then a higher entry in $\boldsymbol{\gamma}$ increases the demand for that asset since it is a hedging instrument, paying relatively more when the background risk is relatively higher. For instance, if b is similar to bonds then this effect might motivate some investment in bonds that would be missing in mean-variance analysis applied to historical data, where bonds' Sharpe ratios are low compared to stocks as commented in Section 2.3.

Now the target μ is not the only object that might differ across investors. The hedging demand \mathbf{w}_h might depend on the investor since the relevant b might do. There is two-fund spanning of each investor's frontier, but none of the two funds is the safe asset in general. Now the relative weights of risky assets might change with the target μ or investor's risk aversion.

The background risk frontier is a hyperbola on the (δ, ω) space, but that space might depend on the investor. It is more interesting to compare background risk and traditional frontiers on the (μ, σ) space, where the latter is the efficient one. The representation in (10) is very convenient

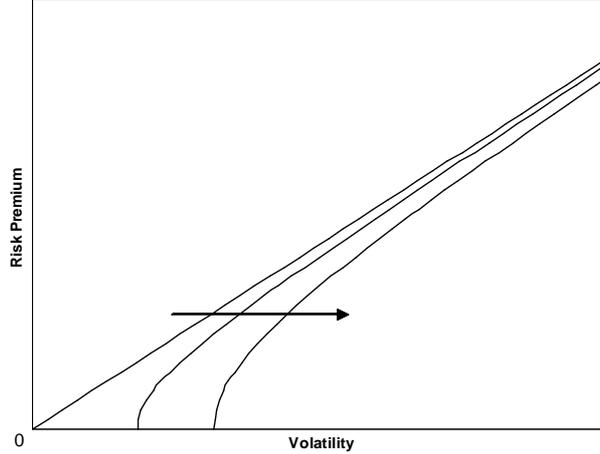

Figure 3: Mean-variance frontiers with and without background risks. The arrow shows the direction of higher hedging demand variance.

for that purpose. In terms of excess returns, $\mathbf{e}'\mathbf{w}_b(\mu) = \mathbf{e}'\mathbf{w}(\mu) + \mathbf{e}'\mathbf{w}_h$ or simply $e_b = e + e_h$. The key property is that e_h is independent of the chosen μ , has a zero mean ($E(e_h) = 0$), and is orthogonal to e ($Cov(e, e_h) = 0$). We find the decomposition

$$Var(e_b) = Var(e) + Var(e_h)$$

and hence the background risk frontier represents a parallel parabola with respect to the traditional frontier on the (μ, σ^2) space, where the size of the parallel movement to the right depends on $Var(e_h)$. The background risk frontier represents a hyperbola with asymptotes equal to traditional lines on the (μ, σ) space. See Figure 3, where the arrow shows the direction of higher hedging demand variance.

The background risk and traditional frontiers coincide ($\mathbf{w}_h = \mathbf{0}$) when the covariance of assets with background risks γ is proportional to $\boldsymbol{\mu}$ since then there is no conflict between the mean-variance and hedging motives. One special case of that situation is a zero covariance γ between assets and background risks. Another special case is the existence of a perfect background risk mimicking portfolio ($b = r_0 + \mathbf{w}'_*\mathbf{e}$ for some \mathbf{w}_*) that lies on the traditional frontier.

Finally, the equilibrium implications will be briefly described. Regarding portfolio advice, the tight link between the market portfolio and the individual portfolios is broken. If b is common across agents then we have two-fund separation and the market portfolio might be chosen as one of the funds, but this does not mean a constant mix of risky assets on the frontier. Moreover, a common b will not be the general case and two-fund separation clearly breaks down with human

capital. Passive management in the sense of holding the market is not the portfolio advice in this set-up.

We should not expect the market portfolio to be mean-variance efficient even in the case of a common b and hence the CAPM equation (8) breaks down. However, given the structure of (10), if we subtract the (average) hedging component from the market portfolio then we have a mean-variance efficient portfolio and hence a properly adjusted market return works in (8).

3.3 Application to Tracking Error Optimization

There is another relevant type of background risk apart from the examples mentioned in Section 3.1. Benchmark-relative investment management is a key ingredient of active portfolio management (i.e. security selection and market timing) as shown in Grinold and Kahn (1999) and Lee (2001). The investment industry usually measures performance relative to a benchmark and a manager might care about her relative performance more than total risk and return.

This section will describe the results of Roll (1992) on tracking error optimization translated to the case of a safe asset. We can easily study this situation in our set-up by interpreting $b = r_0 + \mathbf{w}'_* \mathbf{e}$ as the benchmark, and referring to a as active returns

$$a = r - b = (\mathbf{w} - \mathbf{w}_*)' \mathbf{e} = \mathbf{w}'_a \mathbf{e}.$$

and ω as tracking error (TE)

$$Var(a) = \mathbf{w}'_a \Sigma \mathbf{w}_a = \omega^2,$$

which is a widely used measure of relative investment risk. We will also use the notation $E(b - r_0) = \mu_*$ and $Var(b - r_0) = \sigma_*^2$.

Now we focus on the active portfolio instead of the total portfolio, but the problem is still the same (a self-financing constraint should be added if there was not a safe asset),

$$\min_{\mathbf{w}_a} Var(a) \quad s.t. \quad E(a) = \delta,$$

and the optimal active portfolio can be represented as $\mathbf{w}_a(\delta) = (\delta/H) \Sigma^{-1} \mu$. A noteworthy feature of the optimal active portfolio is its independence from the particular benchmark. Obviously, we can relate (10) to the current representation

$$\mathbf{w}_b(\mu) = \mathbf{w}_a(\delta) + \mathbf{w}_* = [\mathbf{w}_a(\delta) + \mathbf{w}(\mu_*)] + [\mathbf{w}_* - \mathbf{w}(\mu_*)] = \mathbf{w}(\mu) + \mathbf{w}_h.$$

The role of the target δ is simply to scale a vector and the efficient part of the TE frontier on space (δ, ω) is a straight line that starts at the origin. Again, it is more interesting to face

the TE frontier against the traditional frontier on the (μ, σ^2) space, i.e. the mean and variance of $r_b = a + b$ in excess of r_0 . Given the previous representation of optimal TE portfolios,

$$\text{Var}(r_b) = \sigma^2(\mu) + [\sigma_*^2 - \sigma^2(\mu_*)],$$

where $\sigma^2(\cdot)$ is the mean-variance frontier (6) evaluated at a particular target. The TE frontier represents a parallel parabola on the (μ, σ^2) space, it passes through the benchmark and is dominated at all return levels by mean-variance frontier. The distance between both frontiers is equal to the benchmark inefficiency.

TE optimization might be detrimental to overall portfolio efficiency. On the other hand, if b is efficient then both frontiers coincide and TE efficient portfolios are mean-variance efficient. Roll (1992) also comments the introduction of a beta constraint (sensitivity with respect to the benchmark) to decrease the inefficiency of the TE portfolios on the total mean-variance space. Recently, Jorion (2003) studies the introduction of a volatility constraint instead of a beta constraint, while Alexander and Baptista (2005) develop a similar exercise with a VaR constraint.

4 Parameter Uncertainty

4.1 Estimation Error in Mean-Variance Inputs

Assumption 2 states that investors know the true mean μ and variance Σ required in the portfolio choice problem. Obviously, those inputs are uncertain and it is common to simply plug in (5) historical estimates of those parameters by means of a time series of the relevant returns.⁴

Then well-known problems of traditional mean-variance analysis show up: Extreme long/short positions and unstable portfolios, in the sense that a slight change in the target gives significant portfolio changes. Best and Grauer (1991) study the sensitivity in mean-variance portfolios' weights and moments to changes in the means.

The badly behaved portfolios that are found with sample estimates as inputs raise concerns about the estimation error in mean-variance inputs. Michaud (1989) stresses that portfolio optimization based on historical estimates suffers from error maximization. Optimal portfolios take extreme positions that are mainly driven by estimation error, e.g. extremely long in assets with overestimated returns and/or underestimated risk, and hence they perform poorly out of

⁴If one takes seriously the CAPM this is not necessary because the investor should simply hold the market portfolio. This will be exploited in Section 4.3 with the Black-Litterman approach.

sample. Chopra and Ziemba (1993) study the effect of mean and variance errors in portfolios and conclude that mean errors are more important.

On the other hand, there is a difference in the relative magnitude of estimation errors. The variance of returns can be estimated more accurately than their mean if returns follow diffusions as Merton (1980) shows. If we try to estimate the mean and the variance of log-returns by means of their sample counterparts then the standard error of the mean estimator decreases with the data span (say the number of years), while the standard error of the variance estimator decreases with the number of observations. For instance, stock returns are very noisy and an accurate estimation of risk premia would require many years of data, while the estimation of variances can be arbitrarily accurate by increasing the data frequency.⁵

The simplest approach to avoid unreasonable mean-variance portfolios with historical estimates is to impose constraints in the mean-variance optimization (4), e.g. lineal constraints

$$\max_{\mathbf{w}} E(e) - \frac{1}{2\lambda} Var(e) \quad s.t. \quad \mathbf{a}_L \leq \mathbf{A}\mathbf{w} \leq \mathbf{a}_U,$$

for some matrix \mathbf{A} and vectors $(\mathbf{a}_L, \mathbf{a}_U)$. Obviously, this will enforce diversification through portfolios that do not take extreme positions and improve out-of-sample performance as Frost and Savarino (1988) show by means of simulations. More recently, Jagannathan and Ma (2003) point out that short-sale constraints might decrease portfolio risk even when they are wrong (they are not satisfied by the corresponding true portfolio).

A priori, the use of constraints does not look very satisfactory. They are imposed because of the bad quality of the inputs and hence improving their quality should be a more fruitful avenue. However, Jagannathan and Ma (2003) show that certain constraints are equivalent to a modified estimation of Σ that can be interpreted as a shrinkage estimation. This method of estimation is based on a convex combination of a sample estimator and some constrained estimator, and hence the sample estimator is "shrunk" to the constrained one. This estimation tries to find an optimal trade-off between the induced bias and the gain in sampling variance.

Applications of shrinkage estimation to portfolio choice can be found in Jorion (1986) and Ledoit and Wolf (2003). The former computes an optimal shrinkage estimator of the mean that combines the sample mean and a common mean. The latter authors apply shrinkage estimation to the variance, computing the optimal weight between the sample variance and the estimator

⁵This result should be carefully applied. Ait-Sahalia et al. (2005) show that microstructure noise implies an optimal finite frequency, unless that noise is also modelled and estimated. Then the highest frequency is optimal again.

derived from a single-factor model. Jorion (1986) motivates the use of shrinkage estimation in the context of a Bayesian investor, where there is a natural interpretation of such a method, and this will be studied in Section 4.3.

Note that most part of the references of this section are closer to security selection than asset allocation since they study the case of a high N , e.g. construction of a portfolio of many stocks. In that context, there are many unknown parameters and the estimation error has stronger implications. Factor models are the usual choice to handle the high number of parameters in Σ , e.g. Chan et al. (1999) evaluate factor models of Σ in terms of out-of-sample performance of optimal portfolios. The reader can find additional information on shrinkage methods, factor models, and portfolio constraints in Section 3.1.2 of Brandt (2005).

4.2 Sampling Uncertainty in Portfolios

We have followed classic inference in our approximation to our lack of knowledge of the true mean-variance parameters. Let us make explicit what we have done so far in the context of a single risky asset. We have a size T time series of its excess returns (e_1, e_2, \dots, e_T) , which we represent by e^T , and we assume a simple normal model with independent and identically distributed (i.i.d.) observations, i.e. conditional on some value of the parameters (μ, σ^2)

$$e_t \mid (\mu, \sigma^2) \sim N(\mu, \sigma^2), \quad t = 1, 2, \dots, T.$$

We skip the time dependence in returns until Section 6. Since we commented that an accurate estimation of the variance is easier, we assume we know σ^2 to simplify and hence our analysis will be conditional on its value. We are interested in the distribution of the next-period excess return given our information to compute the optimal portfolio. In the previous model, this distribution would be

$$e_{T+1} \mid (\mu, \sigma^2, e^T) \sim N(\mu, \sigma^2)$$

if we knew μ . Unfortunately, we do not know μ and the traditional approach applies a plug-in estimation in the sense of using the distribution $N(\hat{\mu}, \sigma^2)$ with some estimator $\hat{\mu}$. This is a mean-variance framework and the optimal portfolio is given by (5). The estimator $\hat{\mu}$ can be the maximum likelihood one, i.e. the statistic that maximizes $\ln p(e^T \mid \mu, \sigma^2)$ with respect to μ , where $p(\cdot)$ is the likelihood. In the previous normal model, the maximum likelihood estimator is simply the sample mean $\hat{\mu} = \bar{e} = T^{-1} \sum_{t=1}^T e_t$.

If we base the computation of an optimal portfolio on sample data as commented above then the portfolio is a statistic with some sampling error. Jobson and Korkie (1980) studied the estimation of mean-variance portfolios' weights, mean, and variance. They approximate their mean and variance and compute their asymptotic distribution under the assumption of i.i.d. normal returns.

Later, Jobson and Korkie (1983) interpreted the estimation of some mean-variance parameters and mean-variance efficiency tests in an OLS set-up. If we define \mathbf{E} as a $T \times N$ matrix with excess return data and run OLS of a $T \times 1$ vector of ones onto \mathbf{E} , we get the estimator

$$\hat{\mathbf{w}} = (\mathbf{E}'\mathbf{E})^{-1} \mathbf{E}'\mathbf{1} = \left(\frac{1}{1 + \hat{\boldsymbol{\mu}}'\hat{\boldsymbol{\Sigma}}^{-1}\hat{\boldsymbol{\mu}}} \right) \hat{\boldsymbol{\Sigma}}^{-1}\hat{\boldsymbol{\mu}}.$$

We only need to rescale the regression coefficients $\hat{\mathbf{w}}$ to compute the efficient portfolio (5) estimator

$$\hat{\mathbf{w}}(\lambda) = \lambda \hat{\boldsymbol{\Sigma}}^{-1}\hat{\boldsymbol{\mu}},$$

expressed here in terms of risk tolerance λ . The regression framework gives the corresponding standard errors of $\hat{\mathbf{w}}$ and hence we can easily construct confidence intervals and tests on $\mathbf{w}(\lambda)$, e.g. we can test if some entries are significantly different from zero. More recently, Britten-Jones (1999) works with the OLS set-up too and develops finite-sample inference under i.i.d. normal returns.

The bootstrap (or resampling methods) is an alternative approach to evaluate sampling uncertainty.⁶ This approach can be implemented in a nonparametric or a parametric set-up. The former is based on resampling data with replacement (or more refined approaches for time series), while the latter is based on Monte Carlo simulation from a parametric estimate of the return distribution. Jorion (1992) uses the parametric bootstrap implementation assuming i.i.d. normal returns to analyze the sampling variability in optimal portfolios and perform efficiency tests under short-sale constraints.

Michaud (1998) uses bootstrap methods to compute optimal portfolios themselves instead of standard errors, and defines this approach as resampled efficiency. A resampled efficient portfolio associated to some risk tolerance λ is an average of mean-variance efficient portfolios (5) associated to that λ for S different bootstrapped samples with sample moments $(\boldsymbol{\mu}_1, \boldsymbol{\Sigma}_1)$,

⁶See Horowitz (2001) for a survey on bootstrap methods.

$(\boldsymbol{\mu}_2, \boldsymbol{\Sigma}_2), \dots, (\boldsymbol{\mu}_S, \boldsymbol{\Sigma}_S)$

$$\mathbf{w}_r(\lambda) = \frac{1}{S} \sum_{s=1}^S \mathbf{w}_s(\lambda),$$

$$\mathbf{w}_s(\lambda) = \lambda \boldsymbol{\Sigma}_s^{-1} \boldsymbol{\mu}_s, \quad s = 1, 2, \dots, S.$$

The size of bootstrapped samples can be different from the original data to reflect high or low confidence on historical estimates. Resampled portfolios show higher diversification and less sharp changes with respect to λ than traditional mean-variance portfolios, which translates into a better out-of-sample performance. However, this is a heuristic method to deal with estimation error without a theoretical justification as Scherer (2002) points out.

4.3 Bayesian Portfolio Choice

This section will be devoted to a Bayesian treatment of parameter uncertainty instead of the previous classic inference. Bayesian inference is a formal way of dealing with estimation error in problem (3) with a strong foundation in decision theory,⁷ where we study beliefs and learning after observing a sample instead of working with estimators and their sampling distribution. In fact, Markowitz (1952) does not impose that the mean-variance inputs are the true ones and simply works with beliefs.

We return to the simple model at the beginning of Section 4.2, where there is a single normal risky asset and we know σ^2 . This is one of the simplest examples of Bayesian mechanics and hence it might not be a fair representation of its power. On the other hand, this example is enough to motivate the shrinkage estimation commented in Section 4.1 (see (11)) and the Black-Litterman formulas that are shown later in this section. Bayesian inference needs two inputs and produces two outputs:

- Inputs: One input is the data likelihood $p(e^T | \mu, \sigma^2)$, i.i.d. normal returns in our example, which represents the sample information and is common to classic inference. The second input is the prior beliefs $p(\mu, \sigma^2)$, our beliefs about (μ, σ^2) before observing e^T . In our simple example, we know σ^2 and we will use the following prior $p(\mu)$

$$\mu \sim N(\rho_0, \varphi_0),$$

⁷A different approach with axiomatic foundations is robust choice. A robust investor follows a maximin rule, choosing the best portfolio in the worst scenario. See Garlappi et al. (2007) and Lutgens and Schotman (2007) for recent references related to mean-variance analysis.

where the prior mean ρ_0 could be derived through a theoretical model such as the CAPM, and the prior variance φ_0 would measure our confidence in that model.

- Outputs: The first output is the posterior beliefs after observing e^T , $p(\mu, \sigma^2 | e^T)$, which follows the Bayes' rule to combine prior beliefs and sample information.⁸ In our example, we are interested in $p(\mu | \sigma^2, e^T)$

$$\begin{aligned} \mu | (\sigma^2, e^T) &\sim N(\rho_T, \varphi_T), \\ \varphi_T &= \left(\frac{1}{\varphi_0} + \frac{T}{\sigma^2} \right)^{-1}, \quad \rho_T = \varphi_T \left(\frac{\rho_0}{\varphi_0} + \frac{T\bar{e}}{\sigma^2} \right), \end{aligned} \tag{11}$$

where the expression of ρ_T can be interpreted as shrinking \bar{e} towards ρ_0 . On the other hand, these posterior beliefs are not our final object of interest. The portfolio choice problem in (3) requires the distribution of next-period returns given e^T , $p(e_{T+1} | e^T)$, which is the second output and is called the predictive distribution.⁹ The previous i.i.d. normal model states that $e_{T+1} | (\mu, \sigma^2, e^T) \sim N(\mu, \sigma^2)$ and the relevant predictive density $p(e_{T+1} | \sigma^2, e^T)$ integrates out our uncertainty about μ . In this simple model, the predictive distribution is still normal and hence the solution to (3)¹⁰ is the mean-variance solution (5) for the particular mean and variance in

$$e_{T+1} | (\sigma^2, e^T) \sim N(\rho_T, \sigma^2 + \varphi_T). \tag{12}$$

Barry (1974) is one the first references that study the effect of estimating the mean and/or the variance in the predictive distributions of a portfolio choice problem. In those models, we are still in a mean-variance framework and the variance matrix is simply scaled. Therefore, estimation risk changes the selected portfolio but does not change the efficient set. Klein and Bawa (1976) work with non-informative priors, which give a Student-t predictive distribution with similar implications to Barry (1974), but also consider informative priors in special cases

⁸The general expression when we do not know σ^2 is

$$p(\mu, \sigma^2 | e^T) \propto p(\mu, \sigma^2) p(e^T | \mu, \sigma^2),$$

where \propto means proportional to.

⁹The general expression when σ^2 is unknown integrates out both (μ, σ^2)

$$p(e_{T+1} | e^T) = \int_{\mathbb{R}_+} \int_{\mathbb{R}} p(e_{T+1} | \mu, \sigma^2, e^T) p(\mu, \sigma^2 | e^T) d\mu d\sigma^2.$$

¹⁰Some combinations of vN-M utility and Bayesian inference might not give a well defined expected utility. See Geweke (2001) for some examples with CRRA utility.

that change the efficient set. Later, Frost and Savarino (1986) use a Bayesian set-up in the spirit of shrinkage estimators by means of a prior where all means, variances and correlations are equal.

Pástor (2000) and Pástor and Stambaugh (2000) represent more recent references. Their priors are based on factor pricing models and their likelihood is also given by i.i.d. normal returns.¹¹ Pástor (2000) evaluates home bias and value and size effects by means of asset allocation. Pástor and Stambaugh (2000) compare asset pricing models by means of their asset allocation implications when these models are used as priors. They also comment briefly the case of model uncertainty in addition to parameter uncertainty because it can also be incorporated by means of Bayesian model averaging. Tu and Zhou (2004) extend the Pástor and Stambaugh (2000) framework to returns that follow a Student-t with unknown degrees of freedom.

De Miguel et al. (2005) face the out-of-sample performance of a very simple rule, the "naive" diversification rule $\mathbf{w} = N^{-1}\mathbf{1}$ (with and without rebalancing), against several static and dynamic portfolio construction methods, e.g. Bayesian methods. They study different data sets of stocks and bonds and conclude that the simple rule is not inefficient, e.g. it generally delivers the highest Sharpe ratio. The length of the estimation window needs to be quite big to alleviate the estimation error and improve with respect to the simple rule.

We have only commented computations and references related to portfolio construction, but not to the corresponding equilibrium implications. Lintner (1969) represents one of the first approximations to equilibrium under heterogenous expectations in a mean-variance set-up. He shows that the CAPM holds with "market representative" beliefs even though that agents hold different portfolios. Barry and Brown (1985) study the beta implications of a Bayesian set-up where there is more information available for some assets than others and also different information across agents. However, beliefs are exogenous in those references and hence they do not define a rational expectations equilibrium. The book Brunnermeier (2001) is a good introduction to the complex issue of asset pricing under asymmetric information, while Easley and O'Hara (2004) is a recent reference of a rational expectations equilibrium in a mean-variance set-up.

The rest of this section will be devoted to the Black-Litterman approach, which is similar in spirit to the Bayesian approach and is widely used in the industry nowadays. Black and

¹¹Pástor and Stambaugh (2002) develop a different application of factor models to investment in equity mutual funds. They try to disentangle mispricing from manager's skill.

Litterman (1992) consider the historical variance as a good estimator, but not the sample mean. They estimate the risk premia by means of a combination of equilibrium and individual views, in such a way that the market portfolio acts as a well-behaved anchor.

Our exposition will mainly follow He and Litterman (1999). The reader can find a revision of several investment management issues under this approach in Litterman (2003) and the introduction of additional views on volatilities and correlations in a slightly different set-up in Qian and Gorman (2001). Let us return to our general situation of N risky assets and describe the inputs and outputs of this approach:

- Inputs: An equilibrium model and investor's views. The first input defines beliefs on risk premia as

$$\boldsymbol{\mu} \sim N\left(\boldsymbol{\pi}, \tau \hat{\boldsymbol{\Sigma}}\right),$$

where $\hat{\boldsymbol{\Sigma}}$ is some estimated variance matrix of excess returns using historical data, τ reflects the degree of (lack of) confidence on equilibrium returns (we might choose it as T^{-1} , where T is interpreted as a sample size), and $\boldsymbol{\pi}$ is the vector of implied risk premia from the market portfolio. For some plausible market risk tolerance λ_M , we can invert the mean-variance portfolio choice (5) evaluated at the market portfolio \mathbf{w}_M

$$\boldsymbol{\pi} = \left(\frac{1}{\lambda_M}\right) \hat{\boldsymbol{\Sigma}} \mathbf{w}_M,$$

which is an equivalent expression to the CAPM equation (8) if we note that $\lambda_M = \sigma_M^2 / \mu_M$. The second piece of information is expressed as some subjective views on risk premia. The investor might have several views on linear combinations of risk premia (given by the matrix \mathbf{Q}) that we can express by means of

$$\mathbf{Q}\boldsymbol{\mu} \sim N(\mathbf{q}, \boldsymbol{\Omega}),$$

where $\boldsymbol{\Omega}$ reflects the degree of confidence on those views. This matrix is usually chosen to be diagonal and its diagonal entries can be composed by scaled historical variances as we commented above for $\tau \hat{\boldsymbol{\Sigma}}$.

- Outputs: The equilibrium information might be interpreted as the prior beliefs and the subjective views as additional information. Both pieces of information are combined into

a posterior-like distribution of risk premia

$$\begin{aligned} \boldsymbol{\mu} &\sim N(\boldsymbol{\pi}_c, \boldsymbol{\Sigma}_c), \\ \boldsymbol{\Sigma}_c &= \left[\mathbf{Q}'\boldsymbol{\Omega}^{-1}\mathbf{Q} + (\tau\hat{\boldsymbol{\Sigma}})^{-1} \right]^{-1}, \quad \boldsymbol{\pi}_c = \boldsymbol{\Sigma}_c \left[\mathbf{Q}'\boldsymbol{\Omega}^{-1}\mathbf{q} + (\tau\hat{\boldsymbol{\Sigma}})^{-1}\boldsymbol{\pi} \right], \end{aligned}$$

which is similar to (11) in a general Bayesian framework. The corresponding predictive-like distribution is normal and similar to (12)

$$e_{T+1} \sim N\left(\boldsymbol{\pi}_c, \hat{\boldsymbol{\Sigma}} + \boldsymbol{\Sigma}_c\right).$$

The portfolio advocated by this approach applies (5) to that distribution

$$\mathbf{w}_c(\lambda) = \lambda \left(\hat{\boldsymbol{\Sigma}} + \boldsymbol{\Sigma}_c \right)^{-1} \boldsymbol{\pi}_c$$

and the computed portfolios are not as extreme as in the traditional mean-variance analysis. If there is a low confidence in subjective views with respect to equilibrium (or simply neutral views) then the investor holds the market portfolio. Specifically, as $\boldsymbol{\Omega}$ grows without bound there is more weight in equilibrium vs. views and $\mathbf{w}_c(\lambda)$ converges to $\lambda \left(\hat{\boldsymbol{\Sigma}} + \tau\hat{\boldsymbol{\Sigma}} \right)^{-1} \boldsymbol{\pi} = (\lambda/\lambda_M)(1+\tau)^{-1}\mathbf{w}_M$.

5 Beyond Mean-Variance Preferences

5.1 From Expected Utility to Moments of Returns

Our general approach to portfolio choice has been the expected utility paradigm, represented by (3). Now we are going to study the connection between expected utility and the properties of returns distributions. We can express a general vN-M utility function $u(\cdot)$ through its Taylor expansion around the mean of the portfolio return R and take expectations

$$\begin{aligned} E[u(R)] &= u(1+v) + \left(\frac{1}{2}\right) \frac{d^2u(1+v)}{dr^2} E[(r-v)^2] \\ &+ \left(\frac{1}{3!}\right) \frac{d^3u(1+v)}{dr^3} E[(r-v)^3] + \left(\frac{1}{4!}\right) \frac{d^4u(1+v)}{dr^4} E[(r-v)^4] + \dots, \end{aligned}$$

assuming the utility function is smooth enough and the moments finite. Therefore, expected utility depends on the mean, variance, skewness, kurtosis, etc. of portfolio returns.

There are two cases where we can rely on the mean and variance and skip the rest of moments, i.e. $E[u(R)] = U(\nu, \sigma^2)$ as in Section 2.2. Regarding the vN-M utility $u(\cdot)$, if this function is quadratic then the investor is only concerned about her portfolio's mean and variance. However,

this utility is not a plausible description of investor behaviour since it shows decreasing marginal utility from some point and increasing absolute risk aversion (hence a risky asset is an inferior good).

The second case relies on the distribution of returns. If returns are multivariate normal and hence final wealth is normal, $R \sim N(1 + \nu, \sigma^2)$, then mean and variance fully describe the relevant distribution. In fact, mean-variance analysis is not only constrained to normal returns. Risky assets following a multivariate elliptical distribution is a more general justification as Chamberlain (1983) showed. He also showed that if a riskless asset is not available then even a more general distribution is consistent with mean-variance analysis. Owen and Rabinovitch (1983) studied the link between elliptical returns and mean-variance analysis too.

The fact that a Student-t distribution (with a well defined variance) is also compatible with mean-variance analysis points out that it is skewness (asymmetry), but not kurtosis (fat tails) the actual problem for the use of variance as an accurate measure of risk. Skewness is problematic when we work with options or limited liability at a theoretical level. In addition, there is a considerable amount of empirical evidence on asymmetric returns documented by the references of this section.¹² However, Peiró (1999) questions such evidence with daily returns of some stock markets and currencies. The usual empirical evidence against symmetry is based on sample skewness, but this test might not be quite reliable under non-normal distributions and he does not find clear evidence against symmetry when using other types of tests. On the other hand, those tests are based on i.i.d. log-returns, while Sánchez-Torres and Sentana (1998) use a skewness test that does not rely on i.i.d. normal returns. More recently, Bai and Ng (2005) propose similar moment tests of skewness and kurtosis with time series data that are easy to apply.

Nevertheless, we can still rely on mean-variance analysis as an approximation to choices under expected utility. We can interpret mean-variance preferences $U(\nu, \sigma^2)$ as the second order approximation

$$E[u(R)] \simeq u(1 + \nu) + \left(\frac{1}{2}\right) \frac{d^2 u(1 + \nu)}{dr^2} \sigma^2$$

and its ranking accuracy will depend on the vN-M utility function and return distribution. This is an empirical question that will depend on the particular situation under study, e.g. the asset

¹²This refers to the plausibility of normal univariate returns, but there is a multivariate dimension of asymmetry that is not always made explicit. For instance, Ang and Chen (2002) find asymmetric correlation in equity portfolios, in the sense of a higher correlation between individual US stocks and the aggregate US market for downside moves than for upside moves.

classes and the horizon that is considered. Now we will focus on the former example since the role of the investment horizon will be analyzed in Section 6.1.

Levy and Markowitz (1979) find that the approximation performs well in terms of ranking mutual funds. Kroll et al. (1984) extend the analysis to portfolio choice with stocks and compare the corresponding optimal portfolio, showing that mean-variance analysis works well with non-normal returns. Hlawitschka (1994) also extends Levy and Markowitz (1979) in an application to derivatives, which are clearly non-normal. He shows a high rank correlation between mean-variance and other preferences and points out that third and fourth-order Taylor expansions do not necessarily improve the portfolio choice.

There are asset classes such as of emerging markets' stocks and bonds, and more recently hedge funds, that might be quite attractive in mean-variance terms due to low correlations with other asset classes and high Sharpe ratios. But this analysis forgets that they might have a significant negative asymmetry (and high kurtosis) and the investor might dislike it. Bekaert et al. (1998) study asset allocation with cash, stocks and emerging markets when the investor has power utility. On the other hand, Fung and Hsieh (1999) show an application to hedge-funds where mean-variance analysis preserves approximately the ranking of other preferences.

Harvey et al. (2004) and Jondeau and Rockinger (2006) are two recent references of portfolio choice without mean-variance preferences. Harvey et al. (2004) analyze the Bayesian portfolio choice of Section 4.3 in this new set-up. They use a skew normal distribution to model returns, which gives both asymmetry and fat tails. Jondeau and Rockinger (2006) use Taylor expansions of expected (exponential) utility up to fourth order to easily handle asset allocation that takes into account skewness and kurtosis. Mean-variance portfolios are close to the optimal ones with weekly data on stock indices of different regions. However, they are a bad approximation with weekly data on individual stocks unless risk aversion is low, while introducing skewness and kurtosis alleviates the problem.

Finally, let us comment the equilibrium implications of a framework that does not rely on mean-variance preferences. Ingersoll (1987) dedicates Chapter 6 to mutual-fund separation results under restrictions on vN-M utilities or return distributions, and their respective pricing implications. That chapter gives the relevant references for a series of important issues: Two-fund separation holds under more general set-ups than quadratic vN-M utility and/or elliptical returns and there are non-elliptical distributions such that the CAPM holds; on the other hand,

some of the results that look natural in a mean-variance set-up are no longer true for general preferences, e.g. the efficient portfolio set is not necessarily convex and hence the market portfolio might be inefficient.

Rubinstein (1973) is one of the first references that extended the CAPM to preferences that take into account additional moments. Krawss and Litzenberger (1976) start from preferences that depend on the first three moments of returns and develop a pricing equation similar to (8) that requires a new term of coskewness with the market. Simaan (1993) introduces skewness in a factor model of returns, where there is three-fund separation. The third fund is related to skewness risk, and this translates into an additional term in the pricing equation (8). More recently, Harvey and Siddique (2000) take into account coskewness with the market as an additional pricing factor.

5.2 Lower Partial Moments

The previous section studied the connection between mean-variance preferences and expected utility, stressing that skewness is missing in mean-variance analysis, as already mentioned by Markowitz (1952). If two assets with the same mean and variance have different skewness then we expect that an investor prefers the one with higher (positive) skewness.

There have been several approaches that introduce preference for positive skewness in a set-up as close as possible to mean-variance analysis. For instance, Ingersoll (1975) introduces skewness as a third dimension in the analysis and recently De Athayde and Flôres (2004) characterize the efficient set in such a context. This section will focus on a different approach that also follows the mean-variance spirit.

We can consider variance as an overall or absolute risk measure, in the sense that it takes into account both positive and negative outcomes. Unfortunately, the variance is not an accurate risk measure in general. Now we will translate the problem (4) to downside risk measures, i.e. we will understand risk as falling below a reference point or shortfall risk. Specifically, we can use a lower partial moment (LPM) for a reference point r_* and order k

$$LPM_k(r_*) = E \left[[Max(r_* - r, 0)]^k \right] = E \left[(r_* - r)^k I(r \leq r_*) \right],$$

where $I(A)$ is the indicator function that returns 1 if A is true and 0 otherwise. The reference point r_* can be the risk-free rate, a benchmark, inflation, etc.

The choice of $k = 0$ gives $LPM_0(r_*) = \Pr(r \leq r_*)$, the shortfall probability, which was al-

ready proposed by Roy (1952) as the safety first approach. A related but different approach is to choose value-at-risk (VaR) as the risk measure, i.e. the quantile given by a left-tail probability, which has become the most famous downside risk measure in risk management. Alexander and Baptista (2002) study portfolio choice under mean-VaR preferences, characterizing the corresponding frontier and the equilibrium implications.

Bawa (1978) extended the approach in Roy (1952) to a general k -order LPM and studied the relationship of such a decision rule with stochastic dominance. Chapter 2 of Huang and Litzenberger (1988) describes stochastic dominance, a criterion to discriminate portfolios under the expected utility paradigm that is only based on the signs of the derivatives of an otherwise general vN-M utility function $u(\cdot)$ (e.g. a risk averse investor). Obviously, this criterion is much more general than mean-variance analysis, but it is not a practical rule, while LPMs represent a computable approximation. Bawa considers LPMs as a better risk measure than variance for that reason. More recently, Daniélsson et al. (2006) revise the connection between stochastic dominance and several (overall and downside) risk measures.

An obvious critique to $k = 0$ is that it does not take into account the level of underperformance. However, $k = 1$ does since $LPM_1(r_*) = \Pr(r \leq r_*) E[r_* - r | r \leq r_*]$ and the underperformance average shows up. The conditional mean term in $LPM_1(r_*)$ is related to concepts such as expected shortfall, conditional VaR, tail conditional expectation, or expected tail loss in risk management. The reader can find their precise definition in Daniélsson et al. (2006) and an application of mean-conditional VaR choice to hedge funds in Agarwal and Naik (2004).

We can also criticize the choice of $k = 1$ since it shows risk neutrality under r_* . Mean-LPM preferences can be represented with expected utility by means of a vN-M utility $u(R) = R - \theta(r_* - r)^k I(r \leq r_*)$ for some $\theta > 0$, with a corresponding expected utility $E[u(R)] = (1 + \nu) - \theta LPM_k(r_*)$. A general order k is linked to risk aversion in the sense that $k = 1$ separates risk-seeking from risk-averse behaviour for $r \leq r_*$. If we move to $k = 2$ then we find the shortfall semivariance $LPM_2(r_*)$, already commented by Markowitz (1959) as a more robust risk measure. The concept of semivariance is sometimes reserved for $r_* = E(r)$. Note that $LPM_2(E(r)) = 0.5\sigma^2$ under a symmetric distribution and hence the portfolio ordering would be the same using mean-variance preferences.

Let us focus on $r_* = r_0$ and the semivariance $LPM_2(r_0)$. Then we can express the optimal

portfolio in a mean-LPM framework as the solution to

$$\min_{\mathbf{w}} LPM_2(r_0) \quad s.t. \quad E(e) = \mu.$$

Hogan and Warren (1972) develop some theoretical results about the mean-semivariance frontier without a safe asset and a general r_* . They show that $LPM_2(r_*)$ is convex and continuously differentiable in \mathbf{w} . Therefore, this is a standard optimization problem even though we do not have an explicit solution like in the mean-variance context (5). In addition, the frontier is convex on the $(\nu, LPM_2(r_*))$ space. Hogan and Warren (1974) study the existence of a riskless asset and $r_* = r_0$. The concepts of two-fund spanning and tangency portfolio apply also in this context and the efficient frontier is a straight line on the $(\mu, LPM_2^{1/2}(r_0))$ space, i.e. we find a similar situation to Figure 2.

Bawa and Lindenberg (1977) comment similar results for the order $k = 1$ too when $r_* = r_0$, while Harlow and Rao (1989) analyzed a general r_* . Harlow (1991) reviews the mean-LPM analysis and studies an empirical application to international asset allocation, where he finds a higher investment in bonds than with mean-variance preferences. Sortino and Forsey (1996) advocate the use of the semivariance but comment some problems with its implementation.

Finally, let us describe the equilibrium implications of mean-LPM preferences. Hogan and Warren (1974) study the translation of the CML and SML to the mean-semivariance context when $r_* = r_0$. As expected from previous comments about the mean-semivariance frontier, there is two-fund separation using the safe asset and the market portfolio, and the main novelty is that the pricing equation (8) should use a different beta. Its numerator should be the cosemivariance with the market, where the truncation is $e_M \leq 0$ (note that the cosemivariance is not a symmetric concept, while the covariance is), and its denominator should be the market semivariance.

Bawa and Lindenberg (1977) comment similar results for the order $k = 1$ too when $r_* = r_0$, while Harlow and Rao (1989) analyzed a general \tilde{r} . They also develop an econometric implementation of the model and their empirical results show that this model performs better than the traditional CAPM. More recently, Pedersen and Satchell (2002) review the equilibrium implications of mean-LPM preferences as a generalization of a quadratic vN-M utility instead of elliptical distributions. Their motivation is that the CAPM holds under two-fund separating distributions, which are more general than elliptical distributions, and hence the mean-LPM pricing does not add value in those situations.

5.3 Alternative Performance Measures to the Sharpe Ratio

Our last comments on developments beyond mean-variance preferences will be devoted to some alternatives to the Sharpe ratio, defined in (7). The main goal of these performance measures is to give a similar ranking to Sharpe ratios when returns are symmetrically distributed, while showing a preference for skewness when they are not. Moreover, performance measures can be used to guide portfolio choice since they can be used as the criterion to maximize.

A natural generalization of the Sharpe ratio of a risky security is the Sortino ratio

$$S(r_*) = \frac{v - r_*}{LPM_2^{1/2}(r_*)},$$

which is based on the semivariance for some threshold r_* as the risk measure. Pedersen and Satchell (2002) study the theoretical foundations of this measure and advocate the use of $r_* = r_0$. In that context, we commented that the efficient frontier satisfies the properties of two fund spanning and linearity on the $(\mu, LPM_2^{1/2}(r_0))$ space. This linearity provides a single optimal trade-off between risk and return that can discriminate portfolio efficiency.

A different performance measure based on the ratio of upper to lower partial moments of order $k = 1$ is proposed in Keating and Shadwick (2002). However, it is actually a function of the threshold r_* and it lacks a theoretical justification. They define the Omega function by

$$\Omega(r_*) = \frac{E[\text{Max}(r - r_*, 0)]}{E[\text{Max}(r_* - r, 0)]} = \frac{UPM_1(r_*)}{LPM_1(r_*)}$$

and study its properties. Its ranking of assets with different variance, skewness, or kurtosis depends on r_* , e.g. omega might increase with variance when r_* is high.

Stutzer (2000) develops a performance measure that is based on the hypothesis that a fund manager is averse to receiving a nonpositive time-averaged excess return above some benchmark. Specifically, her objective is to minimize the probability of underperformance over the next T periods, which is $\Pr(\bar{e} \leq 0)$ if we assume that the benchmark is the risk-free asset. This criterion follows the spirit of Roy's safety-first approach.

If portfolio returns are i.i.d (which can be generalized) and satisfy $\mu > 0$ then a law of large numbers shows that $\Pr(\bar{e} \leq 0) \simeq 0$ for a high horizon T . This fact is not very useful to order portfolios and a central limit theorem does not provide a good approximation to that probability. But we can rely on the large deviation theory instead, which gives the rate of decay of that probability by means of the moment generating function of e (assuming it is well defined)

$$\Pr(\bar{e} \leq 0) \simeq \exp(-I \cdot T), \quad I = \max_{\theta} -\ln E[\exp(\theta e)].$$

The rate of decay $I \geq 0$ ($I > 0$ if $\mu > 0$, and $I = 0$ otherwise) is the proposed performance index and gives the same ranking as the Sharpe ratio under normality because $I = 0.5SR^2$ in that case. Stutzer faces the portfolio choice among several stocks based on I against a Sharpe ratio criterion and finds that the portfolio chosen by I shows some skewness preference that is not taken into account by the Sharpe ratio.

The usefulness of these alternatives is an empirical question. Recently, Eling and Schumacher (2007) face the Sharpe ratio ranking of hedge funds against twelve alternative measures that include Omega and the Sortino ratio for instance. Hedge funds are clearly non-normal, but the Sharpe ratio gives a ranking that is similar to the other measures.

6 Multi-Period Choice

6.1 Long-Term Choice and Predictability

We have assumed a particular horizon in the previous sections but we have not been explicit about its length. Now we will study the effect of the horizon, which will be denoted by T periods, in buy-and-hold strategies. A textbook treatment of the following concepts can be found in Chapter 2 of Campbell and Viceira (2002).

First, we note that there is not a universal long-term portfolio that is optimal for every agent. The growth-optimal portfolio maximizes the expected geometric return $E [T^{-1} \ln (R_1 R_2 \dots R_T)]$ and hence $E [T^{-1} \ln (W_T^g / W_T)] > 0$, where W_T^g is the final wealth from the growth-optimal portfolio and W_T is the final wealth of any other portfolio. If we assume i.i.d. returns and apply the corresponding law of large numbers then the growth-optimal portfolio outperforms any other portfolio in the long run (as T goes to infinity) with probability reaching one.

However, this choice does not necessarily maximize expected utility for preferences different to vN-M log-utility $u(R) = \ln R$. Similarly, we can translate this argument to a mean-variance context because $E(\ln R) \simeq (1 + \nu) - 0.5\sigma^2$ and hence its maximization is optimal for a risk tolerance of 1 (see the λ representation of (4)), which represents a fairly aggressive investor. Stutzer (2003) is a related reference where the application of large deviation theory in Stutzer (2000) is linked to long-horizon portfolio choice.

Another natural question is the behaviour of the mean-variance frontier as the investment horizon lengthens.¹³ The frontier does not change with the number of periods T when returns

¹³Another interesting (but slightly different) question on horizon effects is the shape of the distribution of returns, which is related to Section 5.1. Arditti and Levy (1976) studied skewness in multi-period returns under i.i.d. returns. More recently, Levy and Duchin (2004) use goodness-of-fit tests of several models at different

are i.i.d. To simplify, let us assume a single risky asset, say the stock market, and that long-term returns are approximately equal to the sum of short-term returns. Then the efficient portfolio (5) for horizon T expressed in terms of risk tolerance λ is

$$w(\lambda) \simeq \lambda \frac{\mu T}{\sigma^2 T} = \lambda \frac{\mu}{\sigma^2},$$

i.e. it is independent of horizon since both risk premium and variance grow linearly with time in this random walk context. Obviously, the previous expression is an approximation and there might be some horizon effects, but they are not relevant in practice. In fact, the previous expression is exact if the risky asset follows a diffusion in continuous time.

However, the Sharpe ratio of the previous portfolio is $SR \simeq \sqrt{T}\mu/\sigma$ when returns are uncorrelated, i.e. it increases with time. Obviously, this behaviour should not be confused with some sort of time diversification. Sharpe ratios should be compared across assets for a given horizon, not across different horizons for a given asset.

On the other hand, there are some empirical examples of clear time series dependence in financial returns: Interest rates are autocorrelated and stock returns are conditionally heteroskedastic. Regarding the empirical evidence on predictability and market efficiency, we refer the reader to Chapter 20 in Cochrane (2001) and Chapters 2 and 7 in Campbell et al. (1997). Therefore, we will not think of i.i.d. returns in the rest of the paper and we will take into account the (stochastic) time-variation of investment opportunities in portfolio construction.

The interest rate r_0 and the risky assets' risk premia $\boldsymbol{\mu} = E(\mathbf{e})$ and variance matrix $\boldsymbol{\Sigma} = Var(\mathbf{e})$ should be conditional on the relevant information set and not equal to unconditional values (e.g. writing $E_t(\mathbf{e}_{t+1})$ and $Var_t(\mathbf{e}_{t+1})$, where subscript t denotes conditioning on information up to t). Hansen and Richard (1987) developed a formal framework of mean-variance analysis with conditioning information, which can be considered as the conditional counterpart of Chamberlain and Rothschild (1983). Ferson and Siegel (2001) and Sentana (2005) represent recent applications of this set-up.

Return predictability introduces time series econometric models into portfolio choice. The standard models in financial econometrics can be found in Campbell et al. (1997). The short-term interest rate following an autoregressive process and the stocks risk premium being linear in the dividend yield are examples of standard models in long-term portfolio, and introduce two

horizons for both stocks and bonds. The best fitting distributions change from short to long horizons: Elliptical distributions fit well at short horizons and hence mean-variance analysis would be justified, but some positive skewness is found at long horizons.

of the most usual predictors (or state variables) in this literature, the short-term interest rate and the dividend yield.

Campbell and Viceira (2005) use a vector autoregressive (VAR) model of returns and predictors to analyze the variance and correlation of stocks, bonds, and cash (Treasury-bills) across different horizons. The volatility per period decreases with horizon for stocks and increases for cash, which are signals of mean-reversion and reinvestment risk respectively. The global minimum-variance portfolio is composed of mostly cash for a short horizon and mostly stocks and bonds for a long horizon. Guidolin and Timmermann (2006) analyze the term structure of different risk measures such as VaR and expected shortfall under several econometric models. There are significant differences across models and there is not a clear best model in an out-of-sample forecasting exercise with portfolios of stocks, bonds, and cash.

The rest of Section 6 will study multi-period portfolio choice with rebalancing during the investment horizon, i.e. we are interested now in a sequence of portfolio choices instead of a single (buy-and-hold) choice. We will focus on the theoretically optimal strategy developed in the academic literature in Section 6.2, but we will briefly comment the industry approach here. The reader can find additional details in Sharpe (1987).

The usual practitioner's approach decomposes the dynamic portfolio problem in two parts. The first component is called strategic asset allocation (SAA) and defines a long-term target or benchmark. The computation of such portfolio can follow the previous comments on long-term buy-and-hold strategies. The second component is called tactical asset allocation (TAA) and tilts the portfolio away from the strategic benchmark to take advantage of short-term changes in investment opportunities. These short-term changes are interpreted as inefficiencies or deviations from equilibrium, and hence an opportunity to active management through market timing ("beating the market" with superior information).

We can apply results from previous sections to this framework. We can use mean-variance analysis to compute the SAA and TAA portfolios. For instance, Clarke and de Silva (1998) show a simple exercise with i.i.d. returns and two possible mean-variance regimes, while Flemming et al. (2001, 2003) apply daily volatility timing to futures on stocks, bonds, and gold. TAA is usually implemented with respect to a benchmark, which can follow Section 3.3 and the references therein. The Black-Litterman approach studied in Section 4.3 is also widely used for TAA by the industry, e.g. the market might represent the SAA and the investor's views drive

the TAA.

6.2 Dynamic Portfolio Choice Theory

The theoretical optimal strategy is not based on a long-term benchmark and short-term tilts, but directly defines a sequence of (contingent) portfolios that is optimal given preferences and return dynamics. We are going to study multi-period portfolio choice in continuous time when returns follow diffusion processes because we can compute expressions that are more explicit than in discrete time, and hence we can clarify the difference to one-period choice. R.C. Merton developed the following results in a series of papers that were lately compiled in Merton (2001). Textbook treatments of the following results can be found in Chapter 13 of Ingersoll (1987) (Chapter 11 is dedicated to discrete time portfolio choice) and Chapter 5 of Campbell and Viceira (2002).

Let us assume that investment opportunities change over time depending on a random variable Z , and therefore it is called state variable or predictor. There are N risky assets that do not pay income (only to ease exposition) and their prices are represented by the vector \mathbf{P} . Let us denote by $d\mathbf{Y}$ the vector with entries equal to dP/P for each asset. At each point in time t , prices evolve as

$$d\mathbf{Y} = \boldsymbol{\nu}(Z, t) dt + \boldsymbol{\Gamma}(Z, t) d\mathbf{B},$$

where \mathbf{B} is a vector Brownian process and $\boldsymbol{\Gamma}(Z, t)$ is a lower triangular matrix, and the state variable follows a similar equation for dZ with respect to another scalar Brownian process B_Z . Drifts (e.g. vector $\boldsymbol{\nu}(Z, t)$) and volatilities (e.g. matrix $\boldsymbol{\Gamma}(Z, t)$) only depend on the state variable and time.¹⁴ The instantaneous risk-free rate might change with the state variable and time too, $r_0(Z, t)$.

Let us define some conditional moments, where some expressions do not make explicit the dependence on (Z, t) to simplify notation. The risk premia and the variance matrix are given by

$$\boldsymbol{\mu} dt = E_t(d\mathbf{Y} - r_0 dt \mathbf{1}) = (\boldsymbol{\nu} - r_0 \mathbf{1}) dt, \quad \boldsymbol{\Sigma} dt = Var_t(d\mathbf{Y}) = \boldsymbol{\Gamma} \boldsymbol{\Gamma}' dt,$$

where subscript t denotes the conditioning on information up to t , and the new relevant object

¹⁴ A discrete-time counterpart of returns might help to clarify the stochastic structure. We can think of a return process

$$r_{t+1} = v(z_t) + \sigma(z_t) u_{t+1},$$

where $v(\cdot)$ and $\sigma(\cdot)$ are functions of the state variable z_t (and independent of time to simplify), and u_{t+1} is a standard normal shock. Conditional on z_t , r_{t+1} is normal with mean $v(z_t)$ and variance $\sigma^2(z_t)$. Finally, we can also think that z_t follows an autoregressive process.

is the (conditional) covariance between prices and the state variable

$$\gamma dt = Cov_t (d\mathbf{Y}, dZ).$$

The portfolio problem is defined as follows. At some initial time 0, the investor maximizes expected utility of final wealth at some future time $W(T)$ given a budget constraint. She computes a portfolio strategy defined by the function $\mathbf{w}(W, Z, t)$ that solves the problem

$$\max_{\mathbf{w}} E_0 [u(W(T))] \quad s.t. \quad dW = W [(r_0 + \mathbf{w}'\boldsymbol{\mu}) dt + \mathbf{w}'\boldsymbol{\Gamma}d\mathbf{B}]$$

for some initial wealth $W(0) > 0$. Wealth is also constrained to be positive every time. We could introduce consumption (and think of an infinite horizon) but it is not a key issue for our main points. Note that now $\mathbf{w}(W, Z, t)$ is measured as portfolio weights relative to wealth and represents a continuous rebalancing until time T .

Merton (1969) solved this problem in the case of lack of predictability with dynamic programming. The reader can find in Mossin (1968) and Samuelson (1969) its discrete time counterpart. Merton (1971) made several extensions of Merton (1969) and one of them was the introduction of Z . Cox and Huang (1989) developed an alternative technique to solve the problem that is based on martingales, which is sometimes easier to apply but requires the assumption of complete markets.

Let us follow the dynamic programming approach. Defining the value function as expected utility at the optimum

$$V(W, Z, t) = \max_{\mathbf{w}} E_t [u(W(T))],$$

and denoting partial derivatives of V by subindices, the optimal portfolio is implicitly given by¹⁵

$$\begin{aligned} \mathbf{w}_d &= \lambda_m \boldsymbol{\Sigma}^{-1} \boldsymbol{\mu} + \lambda_h \boldsymbol{\Sigma}^{-1} \boldsymbol{\gamma}, \\ \lambda_m &= -\frac{V_W}{W V_{WW}}, \quad \lambda_h = -\frac{V_{ZW}}{W V_{WW}}. \end{aligned} \tag{13}$$

In general, \mathbf{w}_d depends on (W, Z, t) , but the standard choice of $u(\cdot)$ in the literature is the CRRA type because \mathbf{w}_d depends only on (Z, t) in that case. We have found that the portfolio strategy is the sum of two components. The first component is similar to the one-period solution

¹⁵Putting together the Bellman principle and Itô's lemma, the optimal choice is characterized by

$$V_W \boldsymbol{\mu} + W V_{WW} \boldsymbol{\Sigma} \mathbf{w}_d + V_{WZ} \boldsymbol{\gamma} = 0,$$

plus the corresponding boundary condition given by $u(W(T))$ in our case.

(5) that we find in mean-variance analysis, and is called myopic. $\Sigma^{-1}\boldsymbol{\mu}$ defines a mean-variance portfolio and $\lambda_m > 0$ is related to relative risk tolerance. The second component hedges against changing investment opportunities, and is called intertemporal hedging demand. $\Sigma^{-1}\boldsymbol{\gamma}$ is the portfolio with maximum correlation with the state variable, i.e. a least squares regression, and λ_h is a measure of aversion to changes in the state variable with the same sign as V_{ZW} .

This structure¹⁶ is not far from the optimal portfolio in (10), where background risks introduced a hedging component. Now there is an intertemporal risk instead since we care about the future investment opportunities after the current period. If $V_{ZW} < 0$ we interpret that higher Z describes better investment opportunities (a decrease in V_W). For instance, let us think of such Z as the short-term interest rate. In that context, there is an incentive to buy bonds because $\gamma < 0$. Their price is relatively higher when it is relatively more valuable, a scenario of low interest rates. Therefore, we find a hedging motive to hold bonds that is missing in the traditional mean-variance approach.

The literature describes (13) as SAA and its myopic component as TAA following Brennan et al. (1997), which does not coincide with the industry use of those terms. Let us study cases where the optimal dynamic strategy is equal to the myopic strategy, i.e. where we find a zero hedging component. A first case is i.i.d. returns (plus CRRA utility in discrete time), i.e. $(r_0, \boldsymbol{\mu}, \boldsymbol{\Sigma})$ do not depend on a stochastic Z . But we already commented that this case does not fit empirical evidence. A context with similar implications is simply that shocks to investment opportunities cannot be hedged with available assets, $\boldsymbol{\gamma} = \mathbf{0}$. A second case is vN-M log-utility $u(W) = \ln W$ because then there is no effect of Z on the marginal utility of wealth, $V_{ZW} = 0$. This is the growth-optimal portfolio context, which we commented above and pointed out that represents a very particular type of preferences.

On the other hand, the relevance of the intertemporal hedging will depend on the utility function and the return properties, like the persistence in Z . Markowitz and van Dijk (2003) show an example in discrete time where a simple rule inspired in mean-variance analysis might perform closely to an optimal dynamic strategy, which is much more difficult to compute. As commented in Section 4.3, De Miguel et al. (2005) face the out-of-sample performance of an

¹⁶Note that (13) is still an implicit solution. We must solve a second-order partial differential equation in V to compute the explicit solution, with an analytic solution in few cases. Merton (1971) gives solutions for HARA utility and i.i.d. returns. Kim and Omberg (1996) and Wachter (2002) study some other few cases with closed-form solutions. The former introduce mean-reversion in the drift of a single risky asset, while the latter adds consumption to that context. The addition of consumption requires the assumption of complete markets to get a closed-form solution using the approach in Cox and Huang (1989).

equally weighted portfolio against several static and dynamic portfolio construction methods. They conclude that such a "naive" diversification rule is not inefficient.

Finally, let us describe the equilibrium implications of this set-up. They were studied in Merton (1973) and the main point is the breakdown of two-fund separation. There is three-fund separation in this context since we need a position in cash, the fund given by $\Sigma^{-1}\mu$ and the fund given by $\Sigma^{-1}\gamma$ to replicate any w_d . In general, if there are K state variables then we need $K + 2$ funds to replicate the optimal portfolios.

Therefore, the portfolio advice cannot be simply holding the market and there is not a single optimal mix of risky assets. However, return dynamics are not interpreted as inefficiencies or deviations from equilibrium since they are part of the equilibrium. The corresponding portfolio advice represents a different interpretation of market timing; not active management as "beating the market" through superior information, but neither passive management as "holding the market". Similarly, the asset pricing model cannot rely only on the market portfolio, which is not necessarily mean-variance efficient. The corresponding multifactor asset pricing model is called the Intertemporal CAPM (ICAPM). On the other hand, under any of the (implausible) commented cases that imply zero hedging demands, the traditional CAPM would hold.

6.3 Applications to Dynamic Asset Allocation

This section and the next one describe papers that apply and extend the theoretical framework of Section 6.2. This is one of the areas in finance with a stronger research effort during the last years, mainly spurred by the empirical evidence on predictability developed during the nineties (and the required improvement in computer power). The investment industry will soon become familiar with this literature.

Brennan et al. (1997) is one of the first applications of Merton (1971), solving numerically a model with utility on final wealth. The asset classes are stocks, bonds, and cash and three state variables (short-term interest rate, bond yield, and dividend yield) drive time-variation in expected returns. They compare three strategies to show the difference between SAA and TAA, one with a fixed horizon of 20 years, another with a fixed horizon of 1 month, and a third one with a horizon given by a fixed date. The first one always invests more in stocks than the second one because of mean-reversion,¹⁷ while the second generally invests more in cash than the first

¹⁷When we describe the sign of the hedging demand in this and the next applications, it is assumed that relative risk aversion is higher than one, i.e. we think of an investor that is more risk averse than a log-utility agent.

one because of reinvestment risk. The third strategy converges from the first to the second one.

Campbell and Viceira (2001) explore the commented idea of bonds as a hedging instrument of future interest rates. They study long-term portfolio choice in an infinite horizon discrete-time model with a single source of time-variation in investment opportunities, the short-term interest rate. They use an approximate solution to the portfolio/consumption problem, which is exact under continuous time and unit elasticity of intertemporal substitution. The portfolio of risky assets is constant over time but different from a myopic portfolio, with a positive hedging demand for bonds. The optimal ratio of bonds over stocks increases with risk aversion, which fits the professional advice commented in Section 2.3.

Campbell et al. (2003) apply this type of approximate solution to a discrete-time model where risk premia are also stochastic and the optimal portfolio is an affine function of the state variables. They analyze another conventional advice commented in Section 2.3 too: Long-term investment in stocks because stocks are relatively safer in the long run. Here the formal justification is that stocks can serve as a hedging instrument of their future risk premia: First, in a VAR equation for stocks, the dividend yield coefficient is positive and hence a higher dividend yield implies a higher risk premium, i.e. better investment opportunities or $V_{ZW} < 0$ in our previous notation; second, the covariance between the residuals in the stock and dividend yield VAR equations is negative, which the authors interpret as mean-reversion in stocks and means $\gamma < 0$ in our previous notation. Another reference that explores the portfolio implications of stock predictability is Lynch (2001). He does not treat stocks as a single asset class and works with equity portfolios formed on characteristics such as size and book to market. Therefore, he can study the interaction between predictability and equity characteristics in the optimal strategy.

We have commented intertemporal hedging demands derived from time-variation in interest rates and risk premia, but volatility and learning are also sources of time-variation in investment opportunities. Chacko and Viceira (2005) analyzed the first case in a continuous-time model of portfolio/consumption choice. The precision of stock returns is mean-reverting and higher volatility denotes worse investment opportunities ($V_{ZW} > 0$) while stocks show a leverage effect ($\gamma < 0$). Hence there is a negative hedging demand for stocks, but less important than the ones derived from interest rates and risk premia since volatility is not as variable and persistent. Gomes (2007) is a related reference with a discrete time model.

Parameter uncertainty introduces a hedging demand through learning too. The current estimates of the relevant parameters become state variables and the investor has incentives to hedge their time-variation. Williams (1977) introduced heterogeneity in beliefs about drifts in Merton (1973) with i.i.d. returns. More recently, Brennan (1998) studies the case of learning about the risk premium of a single risky asset in a continuous-time model without predictability and consumption. A higher risk premium denotes better investment opportunities ($V_{ZW} < 0$) while Bayesian learning of the risk premium implies $\gamma > 0$. Hence there is a negative hedging demand due to the risk premium learning. Xia (2001) adds stock predictability and consumption to the previous set-up. She finds a state-dependent relationship between investment in stocks and the horizon and a non-monotone relationship between the position in stocks and the predictor.

6.4 Link to Previous Sections

The final section of this survey is dedicated to papers that study issues such as predictability, dynamic asset allocation, etc. in the set-up of previous sections. We will start with Bayesian portfolio choice (Section 4.3) given its connection with our last point on hedging demands from learning. We will comment non-normal return models (Section 5.1) afterwards and finally background risks (Section 3.1).

- Bayesian portfolio choice: Predictability was missing in Section 4, where we generally assumed i.i.d. returns. Kandel and Stambaugh (1996) study the relevance of stock predictability by means of the asset allocation of a myopic Bayesian investor. They conclude that predictability is relevant even though its statistical evidence based on regressions of stock returns on predictors is weak. Barberis (2000) analyzes long-term portfolio choice by a Bayesian investor who has access to cash and stocks and uses the dividend yield as a predictor. He studies initially the case of buy-and-hold strategies under both i.i.d. and predictable returns. He finds that the investor holds less stocks the higher horizon, i.e. there are horizon effects for i.i.d. returns in a Bayesian set-up. He studies dynamic strategies and learning too. Avramov (2002) uses Bayesian model averaging to deal jointly with parameter and model uncertainty, where the latter refers to the relevant predictors of stock returns. He applies the model to buy-and-hold strategies of stock portfolios at different horizons. More recently, Hoevenaars et al. (2006) also study buy-and-hold strategies and predictability under a Bayesian (and robust) perspective. Avramov and

Wermers (2006) and Han (2006) are recent references that do not use the standard VAR of the previous references. The former authors analyze investment in equity mutual funds with predictability, while the latter author studies myopic mean-variance strategies with a stochastic volatility factor model that can handle many stocks.

- Lack of a return model: There are two alternative approaches to parameter and model uncertainty that do not need a return model and rely on classic inference. The first one is a nonparametric portfolio estimation and was developed in Brandt (1999). He proposed a kernel estimation of the portfolio/consumption choice in a discrete time model as a function of predictors. Ahit-Sahalia and Brandt (2001) adapt the previous set-up to a context with many predictors, and also take into account both expected and non-expected utility criteria. They build an optimal index that combines the different predictors and study their relative importance. The second approach is parametric in the sense that it models directly portfolio weights as a function of the relevant variables. Brandt and Santa-Clara (2006) apply this method to market timing among asset classes, where the relevant variables are the predictors. Brandt et al. (2004) apply it to security selection among many stocks, where the relevant variables are the stocks characteristics, e.g. market capitalization and book-to-market ratio. The portfolio choice is based on final wealth in both cases, and the first paper is focused on quadratic vN-M utility.
- Markov-switching models: The empirical evidence against normal returns does not mean we should forget about normal distributions since we can still work with a mixture of normal distributions. We can think of returns as switching between "bad times" and "good times", where the former is a low probability regime with higher volatilities, lower means, and higher correlations than the latter. Markov-switching models add persistence in the regimes, as it is the case with business cycles, and hence time-variation in investment opportunities. Ang and Bekaert (2002) show gains from international diversification in dynamic asset allocation even though there is a higher correlation between international stock markets during highly volatile bear markets. They also take into account parameter uncertainty and construct tests on portfolio weights by means of classic inference, e.g. they do not find significant intertemporal hedging. In a similar spirit, Ang and Bekaert (2004) develop other applications but the portfolio strategy is simplified to switching between two mean-variance choices. Guidolin and Timmermann (2007) estimate four different regimes

in a VAR model with large and small stocks, bonds, and cash. They find a non-monotone relationship between the stock position and the horizon due to the interaction between learning and predictability in a dynamic portfolio choice based on final wealth. Guidolin and Timmermann (2005) use two regimes, a CAPM-like model, and preferences defined on the first four moments of wealth. Both features can justify the home bias of a US investor.

- Poisson processes: Section 6.2 was devoted to diffusions in continuous time. In such a context, we can introduce jumps by means of Poisson processes. Merton (1971) already used them in different contexts such as the price of a bond. More recently, Liu et al. (2003) study dynamic asset allocation with utility from final wealth when there are jumps in both prices and volatility of a single risky asset. They compute an analytical solution where the desire to hold leveraged or short positions decreases with respect to the diffusion case. In fact, the optimal strategy can be interpreted as a mixture between a dynamic and a buy-and-hold strategy, as if some component of wealth was illiquid.
- Inflation: Brennan and Xia (2002) focus on portfolio/consumption choice with nominal assets under inflation. They use a continuous time model where the investor has access to cash, stocks and bonds with different maturities. Risk premia are constant but the short-term interest rate and inflation are predictable. They show the effect of horizon and risk aversion on the optimal mix of stocks and bonds and also the chosen bond maturity under short-sale constraints.
- Human capital: There is a brief comment on the impact of wages in Merton (1971). More recently, the impact of human capital in portfolio/consumption choice is studied in Koo (1998) and Viceira (2001). The former uses a continuous time model with several risky securities, while the latter uses a discrete time model with uncertainty about retirement and death and a single risky security interpreted as stocks. In both papers, human capital is exogenous and nontradable, and investment opportunities in financial markets are i.i.d. In the context of a general nontradable asset, Schwartz and Tebaldi (2006) find an analytic solution in continuous time with power utility of consumption and terminal wealth, and a single risky security. Bodie et al. (1992) explore the impact of labor supply flexibility in a continuous time model.
- Housing: Real estate can be traded but its liquidity is much lower than financial assets.

Portfolio choice and asset pricing with an illiquid durable consumption good, which can be interpreted as housing, was analyzed in a continuous time model by Grossman and Laroque (1990). Cocco (2005) and Yao and Zhang (2005) are recent references on the interaction between housing and portfolio/consumption choice. They develop discrete time models that also take into account (exogenous and nontradable) human capital. On the other hand, they only analyze stocks and cash as asset classes and assume that investment opportunities in financial markets are i.i.d.

- ALM: We pointed out that pension funds' ALM has an important dynamic component. We refer the reader to Ziemba and Mulvey (1998) and Scherer (2003) for details. For instance, in the former reference's Chapter 16, R.C. Merton applies the benchmark model of Section 6.2 to university endowment funds, computing the optimal portfolio strategy that takes into account that the university has other (tangible and intangible) assets.
